and Bolu, Turkey, and Boston, Mass

Global warming has direct and indirect effects, as well as short- and long-term impacts on the respiratory and skin barriers. Extreme temperature directly affects the airway epithelial barrier by disrupting the structural proteins and by triggering airway inflammation and hyperreactivity. It enhances tidal volume and respiratory rate by affecting the thermoregulatory system, causing specific airway resistance and reflex bronchoconstriction via activation of bronchopulmonary vagal C fibers and upregulation of transient receptor potential vanilloid (TRPV) 1 and TRPV4. Heat shock proteins are activated under heat stress and contribute to both epithelial barrier dysfunction and airway inflammation. Accordingly, the frequency and severity of allergic rhinitis and asthma have been increasing. Heat activates TRPV3 in keratinocytes, causing the secretion of inflammatory mediators and eventually pruritus. Exposure to air pollutants alters the expression of genes that control skin barrier integrity and triggers an immune response, increasing the incidence and prevalence of atopic dermatitis. There is evidence that extreme temperature, heavy rains and floods, air pollution, and wildfires increase atopic dermatitis flares. In this narrative review, focused on the last 3 years of literature, we explore the effects of global warming on respiratory and skin barrier and their clinical consequences. (*J Allergy Clin Immunol* 2023;152:1033-46.)

Key words: Climate change, global warming, extreme temperature, pollution, epithelial barrier, allergic diseases, asthma, allergic rhinitis, atopic dermatitis

Humanity has been facing an accelerating increase in global temperatures and global warming since the mid-19th century. After the industrial revolution, greenhouse gases such as carbon

Abbreviations used

AD:	Atopic dermatitis
AKR1C3:	Aldo-keto reductase 1C3
AR:	Allergic rhinitis
CO ₂ :	Carbon dioxide
FEV ₁ :	Forced expiratory volume in 1 second
HSP:	Heat shock protein
NO:	Nitric oxide
NO ₂ :	Nitrogen dioxide
O ₃ :	Ozone
PM:	Particulate matter
PM _{2.5} :	PM with diameter 2.5 μm or less
T2R:	Bitter taste receptors
TJ:	Tight junctions
TLR:	Toll-like receptor
TRP:	Transient receptor potential
TRPV:	TRP vanilloid

dioxide (CO₂), methane, nitrous oxide, and fluorinated gases have increased as a result of anthropogenic activities and have caused global warming by trapping excessive heat in the atmosphere.^{1,2} Temperatures are now about 1°C above preindustrial levels, and they continue to rise.³ When high temperatures are combined with high humidity, evaporation decreases and the temperature feels higher than it is—the so-called wet-bulb temperature.^{4,5} A wet-bulb temperature of 35°C is theorized as the threshold for human survival. At wet-bulb temperatures above 35°C, the human body is unable to adapt, causing an increase in both mortality and morbidity.^{4,6} Recent evidence in young, healthy adults suggests that this threshold may be lower, especially in hot and dry climates.⁷

Over the years, heat waves are becoming more common, intense, and prolonged in almost all regions.⁶ Climate change in Asia, Europe, Africa, Australia, and South America is thought to be responsible for regional trends in extreme temperatures.^{4,8,9} The effects of heat waves might be milder for people living in warmer climates because these populations are more acclimatized to higher temperatures, but more frequent extremes in these regions and in densely populated areas pose a serious problem.⁸ On the one hand, more hot and dry conditions cause heat waves, droughts, wildfires, and sandstorms. On the other hand, rising temperatures hold more moisture, changing precipitation patterns and causing heavy rains, floods, and thunderstorms.^{1,2,10}

All these changes pose a risk for respiratory and skin allergies from the prenatal period to advanced age. Increasing temperatures can affect and disrupt the epithelial barriers of the skin and respiratory tracts, directly or indirectly through climatic exposures. Damaged epithelial cells release alarmins, activating the type 2 response and resulting in inflammation. In addition, cholinergic responses are stimulated by activated cytokines and chaperones. As a result of environmental and immunologic interactions, asthma, allergic rhinitis (AR), and atopic dermatitis (AD) are increasingly emerging or exacerbated.^{11,12} Evidence of the direct effects of extreme temperature on epithelial barriers is scarce. Most of the data are provided from *in vitro* studies, cell culture, and mouse models, along with a few human models.

In this narrative review, we highlight the recent and more resounding publications on the effects of climate change, particularly extreme heat and the climatic exposures due to increased temperature, such as heavy rains and floods, air pollution, and wildfires, on the respiratory and skin epithelium. For the airway section, *in vitro* studies, animal models, and human studies with strong and reliable results and highly cited review papers were included by scanning the publications in PubMed, Web of Science, Scopus, and Embase from the last 3 years. For the dermatologic section, most studies were epidemiologic in nature. We searched PubMed for the terms “atopic dermatitis” and any of the terms “climate change,” “extreme heat,” “heavy rains,” “floods,” “air pollution,” or “wild fires” from 2020 to early 2023 and cross-referenced articles. The introduction and conclusion used a combination of the abovementioned approaches to select references.

RESPIRATORY ALLERGIC DISEASES

Composition of respiratory epithelium

The respiratory epithelial barrier, one of the surfaces of the human body in contact with the external environment, is very thin and acts as a physical barrier with mucociliary cleansing and antibacterial functions. The anterior part of the nasal cavity forms a portal for gas exchange with the external environment and is lined with stratified squamous epithelium.¹³ The conductive part from the nasal cavity to the bronchi is lined with pseudostratified columnar ciliary epithelium, goblet cells, and basal cells; terminal bronchi are covered with nonciliary cubic cells (Clara cells), and the alveoli providing gas exchange are lined with thin, flattened simple squamous (type 1 pneumocyte) and cubic (type 2 pneumocyte) epithelium. Goblet cells are the main secretory cells that adhere to each other by tight junctions (TJ), joining between ciliated cells to form a physical barrier against external contaminants.¹³ Neighboring pseudostratified columnar ciliated airway cells are interconnected by TJs. Along with adherens junctions below them, they constitute the zonula adherens and mediate the cephalic propulsion of tracheobronchial secretions by the coordinated action of cilia.^{13,14} Desmosomes on the lateral borders of the cells connect one cell to another. The respiratory epithelium sits on the basal membrane and strongly binds to the underlying extracellular matrix that is formed by the lamina propria.¹⁵ Solitary chemosensory cells such as tuft cells in turbinated tissues of the upper airways, trachea, and proximal airways are close to the nerve fiber, acting as epithelial guards and initiating the productive immune response.¹⁶ Neuronal transient receptor potentials (TRPs) are expressed in epithelial cells and regulate the permeability of barriers. Increased expression of TRP vanilloid 1

(TRPV1) disrupts the epithelial barrier integrity in AR.¹⁶ Moreover, Lee and colleagues have suggested that TRPV4 plays a role in epithelial barrier disruption (Fig 1).¹⁷

After environmental epithelial damage, cross talk between nasal and bronchial epithelial cells and immune cells releases cytotoxic mediators, free oxygen radicals, and collagenases, leading to inflammation and activation of innate and adaptive immune cells.¹⁸ These type 1 and type 2 inflammatory responses open the bronchial epithelial barrier, resulting in increased epithelial permeability.^{15,18}

Extreme temperature events

Extreme heat is roughly defined as a period of high heat in which temperatures are above normal average levels for at least 2 or 3 days.¹⁹ Extreme temperatures have been defined differently in different studies as being above the 90th, 95th, or 97.5th percentile cutoff points for the mean daily temperature.^{20,21} They are associated with more intense heat waves and increase the risk of desertification. The definition of a heat wave differs between regions, depending on how high the measured temperature is above the seasonal average and how many days it lasts.⁹ The probability of a heat wave occurring is 2.8 times greater now than in the preindustrial era. However, the increased risk is much higher in regions where heat waves are infrequent.⁶ For every Celsius degree increase in temperature, the risk of premature death from respiratory disease increases, primarily in vulnerable populations such as the elderly, pregnant persons, and children.² A study of 5896 adults showed that there is a 20 mL decrease in the forced expiratory volume in 1 second (FEV₁) for every 5°C increase in temperature, especially in the winter and spring.²² Urban areas likely have more propensity for extreme heat events compared to rural areas. By replacing natural land covers with closely packed buildings and paved surfaces, temperatures in urban areas are higher than in rural regions.^{2,23} This temperature gradient is a result of increased heat absorption, differences in convection efficiency, and evaporation in urban structures, termed the heat island effect. In addition, high pollution and high traffic-related air pollution levels in urban areas amplify the mortality and morbidity due to heat waves.

Direct effects

Studies about the direct effects of heat stress on respiratory system include mostly *in vitro* studies and animal models (Table I). According to a recent meta-analysis, extreme heat affects the thermoregulatory system; it increases tidal volume, respiratory rate, and systemic inflammatory response.²⁴ In animal models, heat stress was found to directly disrupt the epithelial barrier of the intestine by enhancing TJ permeability, upregulating the structural protein occludin, and downregulating the functional protein zonula occludens 1.²⁵ Because of these findings, we surmised that similar changes could be seen in the respiratory epithelial barrier under extreme heat. This process should be studied in animal and human models. Furthermore, high temperature may aggravate airway inflammation by increasing IL-4, IL-1 β , IL-6, and TNF- α and by shifting the T_H1/T_H2 balance to T_H2, altering mucus production, damaging the airway epithelium, and triggering airway hyperreactivity in mice.²⁶ All these molecular effects detected in animal models give us an idea about the

FIG 1. Healthy and impaired respiratory epithelial barrier. Adjacent pseudostratified columnar ciliated airway cells are interconnected by TJ, adherens junctions, and desmosomes. Respiratory epithelium sits on basal membrane, attached to lamina propria. Neuronal TRPs are expressed in epithelial cells and regulate permeability of barriers. When disrupted by increased temperature, airborne allergens, and pollution, TJ proteins such as zonula occludens–associated occludin, claudin, and JAM are disrupted and epithelial junctions open. TRPV1 and TRPV4 are upregulated; HSP-70, HSP-90, and HSP-72 are increased, and ROS are formed. All these cause increased inflammation, increased paracellular permeability, increased mucus, reduced ciliary movement, damaged cilia, and epithelial shedding. *JAM*, Junctional adhesion molecules; *ROS*, reactive oxygen species.

changes that can be seen in the respiratory epithelial barrier in humans under heat stress.

A study on the ciliated respiratory epithelial cells obtained by nasal brushing from 100 healthy individuals showed that rising temperatures increase the ciliary beat.²⁷ Another study on ciliated airway cells obtained by brushing nasal and airway mucosa from 30 healthy adults showed that the cilia stabilizes after reaching normal motility between 20°C and 45°C, and the motility declined above 45°C.^{28,29} Recently, a comprehensive meta-analysis reported that extreme heat plays a crucial and independent role in the pathogenesis of asthma flares (Figs 1 and 2).²⁴

From the larynx to the alveolar wall, the airway is innervated by vagal sensory nerves mostly composed of unmyelinated (C) afferent fibers expressing neural TRP channels. TRP receptors, especially TRPV1 and TRPV4, are sensitive to hot temperatures, >42°C and 22–40°C, respectively, and are activated by breathing hot air.^{24,30} TRPV1 channels are overexpressed in the airways of patients with refractory asthma and AR; they are activated by chemical mediators during chronic airway inflammation *in vivo* and *in vitro*.^{26,31} In addition to mice models showing that breathing hot air aggravates the airway inflammation, this hypothesis is supported by epidemiologic evidence of heat-induced asthma

TABLE I. Summary of studies on extreme heat exposures and airway outcomes

Study	Study design	Study size	Main outcome/ finding	Strengths	Limitations
Rice (2019) ²²	Cohort study	5896 participants	<ul style="list-style-type: none"> ● Each 5°C higher previous-week temperature was associated with 20 mL lower FEV₁. ● This association was present in winter or spring only. 	<ul style="list-style-type: none"> ● Validated spatiotemporal temperature model using satellite surface temperature data was used to more precisely predict temperature. ● Individual, neighborhood, and seasonal confounders were considered in measurements. 	<ul style="list-style-type: none"> ● Includes only White, middle-age, and older people, so not representative. ● Only 2 repeated measures.
Han (2022) ²⁴	Meta-analysis	111 studies	<ul style="list-style-type: none"> ● Extreme heat increases tidal volume, respiratory rate, and SIR. ● Extreme heat is an independent trigger of asthma exacerbations. ● TRP receptors are activated by breathing hot air. 	<ul style="list-style-type: none"> ● Systematically summarized studies with epidemiologic evidence and clinical implications. 	<ul style="list-style-type: none"> ● Lack of standardization across studies for meteorologic definitions, measurements, and exposure assessment.

attacks.^{24,32} Breathing hot and humid air activates bronchopulmonary vagal C fibers, upregulating TRPV1 and TRPV4, increasing cholinergic responses, and increasing the specific airway resistance and reflex bronchoconstriction.^{24,33-35} There have been few human studies investigating the role of TRPV1 and TRPV4 in thermoregulation,³⁵ and more research is needed. Future studies should investigate the effects of hot air inhalation on TRPV1 and TRPV4 activation in humans.

Heat shock proteins (HSPs), chaperones that are activated in heat stress conditions, increase to protect cells from heat injury. Several *in vivo* and *in vitro* experiments have shown that the effects of HSP-70 on the respiratory epithelium are controversial.^{24,36} Traditionally, it is thought that intracellular HSP-70, a cytoprotective chaperone that has proinflammatory properties, acts as an alarmin when secreted into the extracellular space.³⁶ Proinflammatory HSP-70 can support the allergic airway response and maintains increased levels of IL-4, IL-5, IL-13, and eosinophils.³⁷ It also stimulates the secretion of IL-1, IL-6, and IL-8 by epithelial cells and alveolar macrophages, which amplifies the recruitment of neutrophils to the site.³⁸ However, HSP-70 also has anti-inflammatory properties, preventing neutrophil hyperactivation, downregulating eosinophils, and suppressing allergic cytokines.³⁶ Moreover, higher levels of HSP-70 in Caco-2 cell cultures have been shown to increase occludin levels and decrease epithelial permeability.^{39,40} This finding suggests that HSP-70, which is stimulated in the respiratory tract epithelium by heat, may have similar effects and may have protective effects for the airway epithelial barrier. Further research is needed. Both *in vitro* experiments and human studies showed that when activated by extreme heat, HSP-70/72 prevents cell apoptosis and plays a critical role in the ability of cells to become thermotolerant.³⁹ HSP-90α, which plays a role in heat acclimation, also has an important role in airway barrier dysfunction

and supports the development of asthma in house dust mite-induced asthmatic mice.⁴¹ In cell cultures, HSP-90 has been shown to regulate bitter taste receptor (T2R)-dependent nitric oxide (NO) pathways in primary sinonasal epithelial cells, and its inhibition reduces T2R/NO-driven nasal ciliary beating.⁴² Consistent with a sustained inhibition of the inflammatory response, the nuclear factor kappa-light-chain enhancer of activated B cells (aka NF-κB) pathway, which influences both adaptive and innate immunity, has been shown to be downregulated by heat stress in a study population of young and healthy volunteers exposed to extreme heat for short periods in a sauna (Figs 1 and 2).^{39,43}

Indirect effects

Heavy rains and floods. Excessive evaporation due to increased air temperature causes heavy rains and floods, creating hot and humid conditions that contribute to increased indoor mold contamination.⁴⁴ Molds disrupt the epithelial barrier by secreting proteases and reducing the transepithelial resistance, causing cilia dysfunction, and increasing barrier permeability.^{45,46} In addition, they induce airway inflammation and cause airway remodeling.⁴⁵ Moreover, heavy rainfall increases the atmospheric concentration of allergenic particles such as pollen grains and fungal spores by mechanical impact and fractionation. Independent of humidity and pollution exposure, Nassikas and colleagues found that precipitation was associated with higher fractional exhaled nitric oxide among adolescents with asthma.⁴⁷ In conjunction, multiple studies have demonstrated worsening of AR and asthma after thunderstorms.^{48,49}

Airborne allergens. Increasing temperature, humidity and high CO₂ levels increase the concentration of airborne allergens (ie, pollens, mites, fungi), leading to a longer pollen season

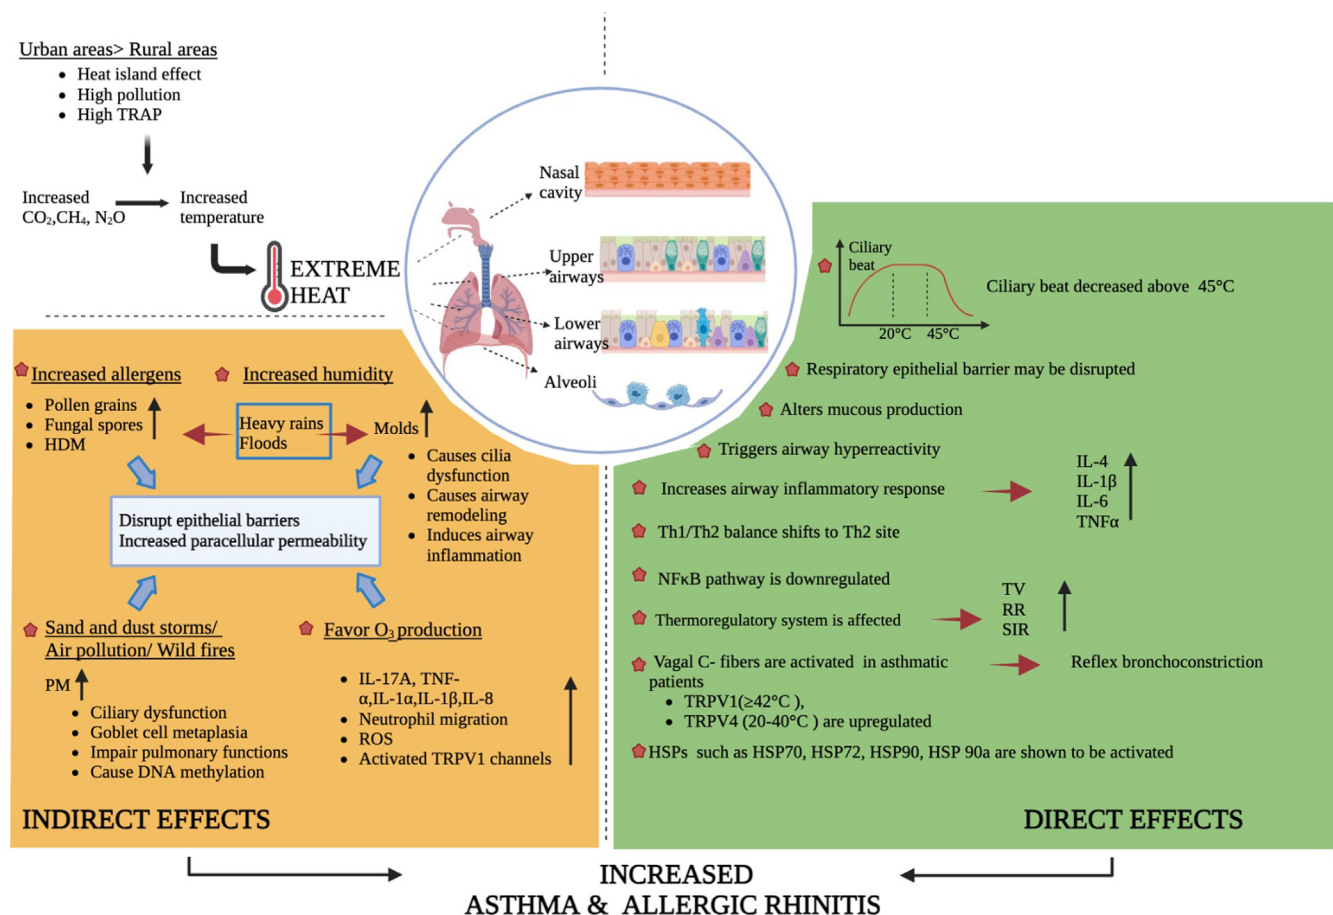

FIG 2. Direct and indirect effects of extreme heat on upper and lower respiratory epithelial barrier. Results are summarized of cell culture, animal models, and human studies; levels of evidence are indicated in text. HDM, House dust mite; ROS, reactive oxygen species; RR, respiratory rate; SIR, systemic inflammatory response; TRAP, traffic-related air pollution; TV, tidal volume.

—and even driving the emergence of new allergenic species.⁵⁰ In addition, air pollutants (ie, nitrogen dioxide [NO_2] and ozone [O_3]) can modify the chemical characteristics of airborne pollen and increase its allergenicity.² Pollen with proteolytic activity such as molds and house dust mites disrupt the epithelial barrier integrity. This facilitates the recognition and presentation of allergens in the respiratory tract, initiating allergic inflammation and leading to the development of sensitivity to other allergens (Figs 1 and 2).⁵¹ Accordingly, a 25-year longitudinal study showed a significant association between increased temperatures and longer pollen seasons, increased peak pollen duration, more severe seasonal AR, and increased hospital admissions.⁵⁰

Air pollution, sand and dust storms, and wildfires. Climate change and air pollution affect the mortality and morbidity of allergic diseases. Increased solar activity, which amplifies the effects of particulate matter with a diameter of 2.5 μm or less ($\text{PM}_{2.5}$), induces reductions in FEV_1 and forced vital capacity.⁵² A recent large study from Europe showed that deaths from lung diseases increase much more when air pollution is combined with high temperatures.⁵³ $\text{PM}_{2.5}$ disrupts both the nasal and the respiratory tract epithelium by reducing TJ proteins, increasing paracellular permeability, causing goblet cell metaplasia, and leading to increased mucus secretion, ciliary loss, and dysfunction.^{16,34,55} On another note, sand and dust storms

are an undeniable cause of air pollution with $\text{PM}_{2.5}$, pollen, chemicals, and microbiologic elements such as bacteria and fungi. They induce neutrophilic and eosinophilic inflammation by either stimulating proinflammatory cytokines and mediators or via Toll-like receptor (TLR)-2- and TLR-4-mediated inflammatory response.^{56,57} $\text{PM}_{2.5}$, particulate matter with a diameter of 10 μm or less, and dust storms have been shown to worsen both AR and asthma clinically.^{58,59} Recently a study from Turkey showed that dust storms increased the risk of mortality, emergency visits, and hospitalization in patients with asthma.⁶⁰

Wildfires destroy ecosystems by absorbing CO_2 from the atmosphere and creating particulate pollution such as dust storms. Zeglinski and colleagues demonstrated the disruptive effects of wildfires on the barrier dysfunction in a human airway epithelium model (Figs 1 and 2).⁶¹ Wildfires have caused specific DNA methylation patterns in nasal epithelial cells, affecting the $\text{T}_\text{H}1$ and $\text{T}_\text{H}2$ activation pathways.⁶² Clinically, in a Brazilian study involving more than 2 million patient records, wildfire-related $\text{PM}_{2.5}$ was associated with a 23% increase in respiratory complaint-related hospital admissions.⁶³

An increased frequency of heat waves leads to increased ground-level O_3 production and exacerbation of surface O_3 pollution events.⁶⁴ Animal models have shown that exposure to O_3 results in shedding of the ciliary epithelium, transcriptional changes

FIG 3. Hypothesized effects of heat and particulate matter on skin barrier structure. Skin is composed of epidermis and dermis; layers and components of these layers are labeled. Heat activates TRPV3 in keratinocytes, increasing TSLP, NGF, and PGE₂. (TRPV3 expression and function is increased in AD.) PM has several hypothesized effects in AD: (1) decreases expression of stratum corneum and TJ-related proteins, (2) induces expression of AKR1C3 (AKR1C3 variant is overexpressed in AD), (3) leads to differential expression of genes controlling skin barrier integrity and immune response, increasing skin inflammation, and (4) results in increased epidermal and dermal thickness and increased dermal inflammation. NGF, Nerve growth factor; PGE₂, prostaglandin E₂; TSLP, thymic stromal lymphopoietin.

in genes related to barrier function, and epithelial organization.^{65,66} O₃ exposure augments TLR-2- and TLR-4-enhanced neutrophil migration, stimulates cytokines including IL-17A, TNF- α , IL-8, IL-1 α , and IL-1 β , activating TRPV1 channels, and forming reactive oxygen species (Figs 1 and 2).^{66,67} Consistent with these results, chronic exposure to O₃ was associated with an increased risk of airway hyperresponsiveness, asthma flares, and even respiratory mortality.^{59,68}

Implications for AR and asthma

In summary, recent reports have revealed the direct and indirect effects of extreme temperatures on the respiratory epithelial barrier. The evidence points to an increased prevalence and risk of AR and asthma exacerbations, hospitalizations, and mortality with climatic exposures. Further studies are needed to

individually elucidate the potential treatment strategies to act on affected mediators, chaperones, receptors, and proteins. In addition, there is a need for translational studies investigating the validity in humans of results obtained in cell cultures or animal models, as well as epidemiologic studies to see the actual effects in populations.

DERMATOLOGIC ALLERGIC DISEASES

Composition of dermatologic epithelium

Skin is divided into 2 major layers, the epidermis and dermis (Fig 3). The epidermis is composed of 4 sublayers—the stratum corneum, stratum granulosum, stratum spinosum, and stratum basale—followed by the basement membrane.⁶⁹ The stratum corneum is important in barrier formation; it is the outer layer containing enucleated keratinocytes called corneocytes. In

addition to the epithelial cells, structural proteins, secreted epithelial products, and microbiota comprise the epidermis. Filaggrin, an important structural protein, aligns the keratin filaments, aiding in the barrier function. TJ prevent transepidermal water loss.⁷⁰ The dermis, below the epidermis, is primarily composed of connective tissue. Fibroblasts function as the primary cells, providing resistance and elasticity through the secretion of collagen and elastin. Nerve endings, sebaceous glands, hair follicles, and blood and lymphatic vessels are embedded within this layer.

Patients with AD have a disrupted skin barrier, thereby allowing allergens and air pollutants entry into the body, triggering a type 2 immune response.⁷¹ Recent reviews offer comprehensive summaries of mechanistic and epidemiologic studies relating to climate change and AD.^{72,73} Much of the data are epidemiologic in nature and provide interesting hypotheses that should be explored further.

Direct effects

Extreme temperature events. One feature of climate change is extreme temperature, especially, as mentioned above, extreme heat events.⁷⁴ Limited data exist on the effect of extreme heat on the skin epithelium. However, heat can trigger itch in AD.⁷⁵ One study examined the role of TRPV3 in heat-induced itch in AD.⁷⁶ TRPV3, a thermosensitive TRP channel, is expressed in keratinocytes and activated by heat. Keratinocytes from patients with AD had increased expression and hyperactive function of TRPV3. TRPV3 activation led to increased secretion of thymic stromal lymphopoietin, nerve growth factor, and prostaglandin E₂, suggesting that TRPV3 is a therapeutic target for heat-induced itch (Fig 3).

The data on the effect of sweat on the epithelial function in the setting of extreme heat is limited and over a decade old,⁷⁷⁻⁷⁹ comprising a mix of *in vitro* and *in vivo* studies. We know that ambient temperature, humidity, and climate affect sweat gland activity.⁸⁰ However, while sweat gland activity increases with increasing temperatures, it is unclear whether skin sweat glands are constitutively active or activated at a certain temperature.^{77-79,81} Furthermore, increased transepidermal water loss, a measure of a disturbed or disrupted skin barrier, is associated with increasing temperature and decreasing relative humidity, although it is more strongly correlated with temperature than humidity.⁷⁷ Studies examining the role of sweat on epithelial barrier function in current climate patterns are needed.

The clinical evidence for the effect of temperature on AD has been inconclusive. A time series analysis found that both low and high temperatures were associated with increased AD outpatient visits, especially in the pediatric age group of 14 years old and younger.⁸² Another time series analysis explored the synergistic effect of heat with pollution.⁸³ This study examined the association between multiple meteorologic factors and over 2 million clinical visits for childhood allergic diseases in 2 large pediatric hospitals in Shanghai, China, over a decade (2007 to 2017); it found that low temperatures and high levels of NO₂, among other factors, were associated with increased clinical visits for childhood AD. A smaller longitudinal study found that higher indoor temperatures and higher relative humidity contributed to higher indoor formaldehyde levels.⁸⁴ The extent to which formaldehyde exposure increased AD symptoms varied according to child age

and indoor temperature. Taken together, these data suggest that extreme temperatures may contribute to AD flares, with limited data suggesting TRPV3 to be a potential therapeutic target in heat-triggered AD (Fig 3).

Indirect effects

Heavy rains and floods. Two recent clinical studies have assessed the effect of heavy rains and floods on skin conditions.^{85,86} The first was a retrospective population-based study using a time-stratified matched-period case-crossover design of children aged 0 to 12 years in Taiwan.⁸⁵ There were increased odds of childhood AD visits on weeks with floods compared to weeks without floods. The second study was a retrospective cross-sectional study of pediatric patients in the Houston area before and after Hurricane Harvey.⁸⁶ Dermatologic complaints were more commonly seen in the 30 days after the hurricane compared to the same period a year before. These time series studies provide initial data supporting an association between floods and AD flares, but more data are needed.

Air pollution. Recent studies have explored the association between air pollution and AD, including 3 mechanistic studies examining the effects of particulate matter (PM) (Fig 3).⁸⁷⁻⁸⁹ Using a mouse model, Woo and colleagues found that exposure to PM with diameter 10 µm or less induces and worsens skin inflammation via the differential expression of genes controlling skin barrier integrity and immune response.⁸⁸ Next, using a mouse model of oxazolone-induced AD-like skin and human keratinocyte cells, Bae and colleagues found that PM downregulates the expression levels of several stratum corneum and TJ-related proteins.⁸⁷ The epidermal and dermal thickness in an AD-like mouse model was significantly increased, and dermal inflammation was prominent in the PM-treated, AD-like skin. Finally, Vogeley and colleagues explored whether genetic susceptibilities modified the effect to which air pollution affects AD.⁸⁹ Their group specifically looked at a gene variant of aldo-keto reductase 1C3 (AKR1C3), which is highly expressed in AD skin, in the GINplus/LISA birth cohort. PM exposure induced AKR1C3 expression in human skin. With chronic PM exposure, each rs12529 single nucleotide polymorphism allele of this gene increased the chance of developing AD by 37% to 38%, suggesting that certain populations may be more susceptible to the effects of pollution on AD.

A wealth of recent epidemiologic information adds to these mechanistic studies by showing an association between air pollution and AD.⁹⁰⁻⁹⁹ We highlight recent longitudinal, time series, and machine learning studies assessing this topic. Several longitudinal studies made up of several thousand participants each have found an association between pollution and AD incidence and symptoms.⁹⁴⁻⁹⁶ Using the Korean National Health Insurance Service–National Sample Cohort database from 2008 to 2013, this study found that long-term exposure to air pollutants, including sulfur dioxide, NO₂, carbon monoxide, and PM, was an independent risk factor for developing AD.⁹⁴ Another study used 13 years of the Taiwan National Health Insurance research database linked to the Taiwan Air Quality Monitoring Database and similarly found that exposure to higher concentrations of total hydrocarbons and methane were associated with an increased risk of childhood AD.⁹⁵ Both studies used more than 5 years' worth of national health insurance data with more than 3000 subjects and independently found an association of pollution with AD

TABLE II. What remains unknown?

incidence. An additional longitudinal study found that indoor concentrations of PM, CO₂, and volatile organic compounds were lower in energy-efficient homes after controlling for seasonality.⁹⁶ CO₂ was associated with daily risk of AD symptoms. Finally, Huang and colleagues used machine learning in a longitudinal birth cohort and found that prenatal air quality was important to predict childhood AD development.⁹⁰ Four time series studies found that various air pollutants, including PM, sulfur dioxide, NO₂, carbon monoxide, and O₃, were associated with an increase in AD visits.⁹⁷⁻¹⁰⁰ This effect was stronger in the cool season and among children and the elderly.^{98,100} Interestingly, a recent study explored the effect of air pollution on patients with moderate-to-severe AD on dupilumab and found a dose-dependent relationship between air pollutants and risk of an AD flare.¹⁰¹ These data are limited as a result of the lack of a control group (ie, patients not receiving dupilumab therapy), so we cannot assess whether dupilumab might provide some protective effect, given its positive effect on restoring the skin barrier.¹⁰² In summary, there is recent robust clinical evidence showing an association between air pollution and an increase in the incidence, prevalence, symptoms, and severity of AD. Next steps should attempt to bridge these studies by providing translational human mechanistic studies of patients affected by air pollution.

Wildfires. There are also limited recent mechanistic studies assessing the effect of wildfires on AD. We reviewed recent epidemiologic studies, which found an association between wildfires and AD flares. Two studies of the 2018 California Camp Fire highlight key findings about the relationship between wildfires and AD.^{103,104} The authors evaluated associations between wildfire air pollution and (1) clinic visits for AD or itch

and (2) prescribed medications for AD management.¹⁰³ This time series study found an increased rate of AD and itch visits for both pediatric and adult patients on weeks with wildfires compared to weeks without wildfires. There was a statistically significant increase in the rate of systemic medication prescription during wildfire weeks among adults with AD. Among adults aged 65 years or older, there were higher rates of clinic visits for itch on weeks with a wildfire.¹⁰⁴ For both this age group and the younger adult age group of 18- to 64-year-olds, there was a significant increase in AD visits on wildfire weeks. Smoke plume density from satellite imaging was also associated with a higher rate of clinic visits for AD in both age groups and for pruritus in the older age group. Future work on the effect of wildfires on AD may focus on elucidating mechanistic pathways through animal or human models.

Implications for AD

Recent studies provide evidence of the effects of climate change—specifically of extreme temperature, heavy rains and floods, air pollution, and wildfires—on AD. Some of these associations need to be studied further to account for confounders and to further elucidate the biological mechanisms, ultimately to better understand how to manage climate change-associated AD exacerbations.

Conclusion

In this review article, we discuss the effects of extreme temperatures resulting from the deterioration of the climate

system. Extreme temperatures adversely affect respiratory and skin barriers by acting directly, or by causing extreme weather events such as heavy rain, floods, dust storms, wildfires, and air pollution. While evidence is limited, these changes appear to disrupt structural proteins that make up the epithelial barriers and the development of inflammation and the activation of cholinergic pathways, contributing to increased frequency and severity of AR, asthma, and AD. Future studies should aim to fill our knowledge gaps of the effects of climate change on atopic disease (Table II).

Individuals, providers, scientists, and legislators should act in unison to combat the climate change crisis and its effects on atopic disease. Future research will illuminate individualized management strategies against the damage caused by global warming. Together, we can all take steps to mitigating the legacy of climate change for future generations.
